# Objectives and motivation

---

- Investigate operation and interaction of QoS mechanisms in IPv6 networks
  - Policing, shaping, queuing
- These mechanisms will be used in customer-provider interface
- Tuning is important for supporting Service Level Agreements (SLAs)
  - Tuning each in isolation not sufficient
- Do they have different performance in IPv6 compared to IPv4?

# User-network interface

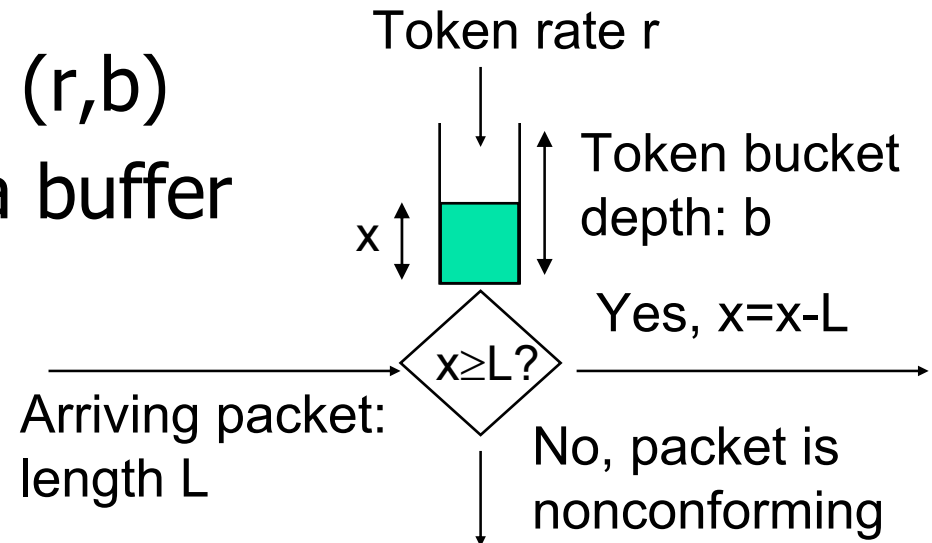

# QoS mechanisms investigated

---

- Cisco Traffic Policing
  - *Committed Access Rate – CAR not supported in IPv6*
- Cisco Generic Traffic Shaping - GTS
- Linux Traffic Policing
- Linux Traffic Shaping
  - Token Bucket Filter – TBF
- Linux Class Based Queuing - CBQ

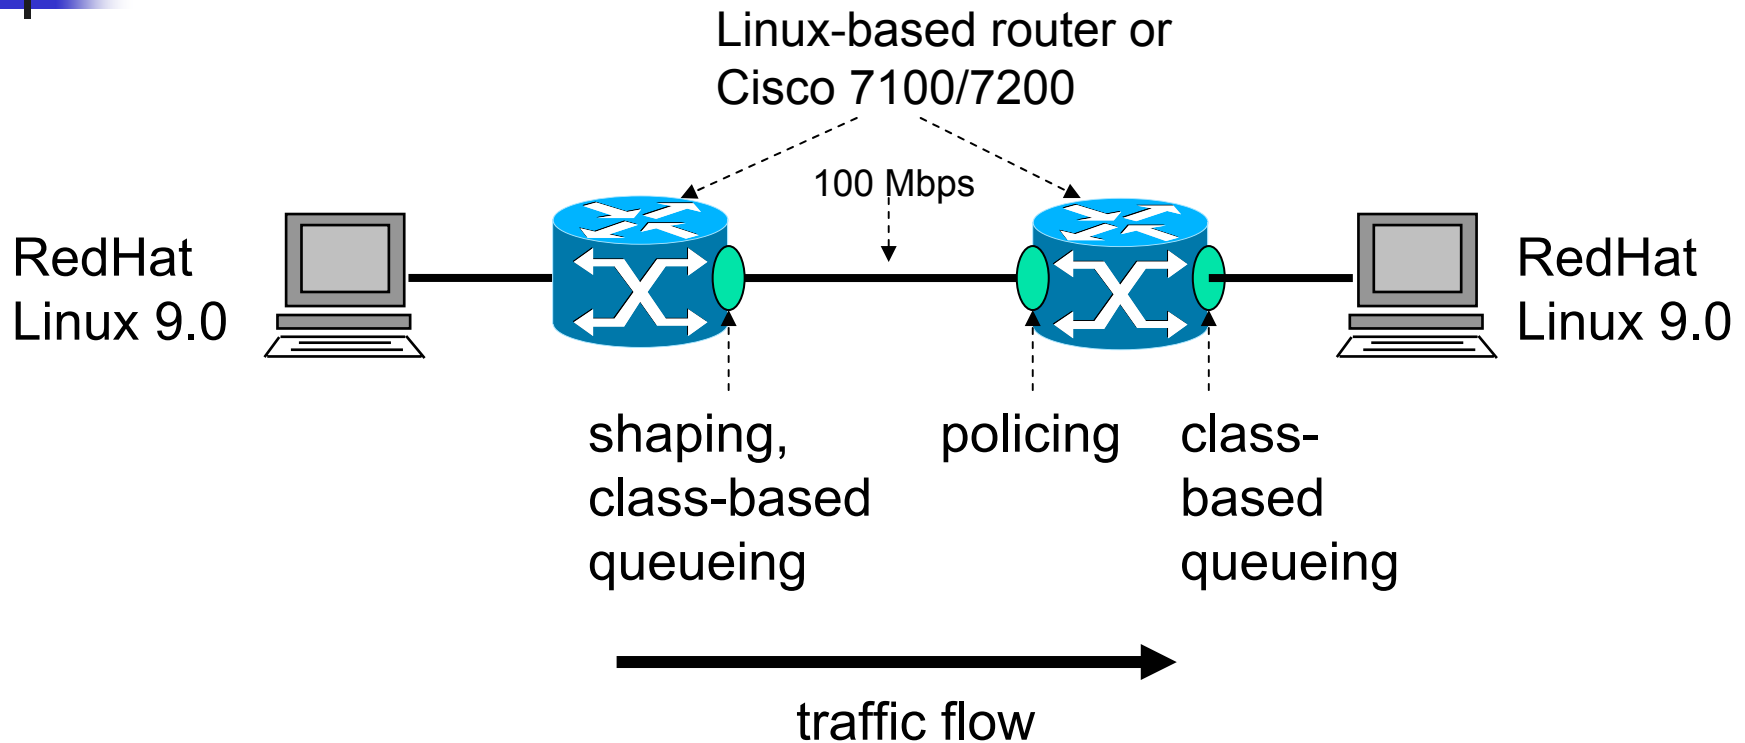

# Token bucket algorithm

- True token bucket  $(r, b)$
- Shaping includes a buffer

- Implementation differs
  - Mean rate or Committed Information Rate (CIR)
  - Committed Burst Size ( $B_c$ )
  - Time interval ( $= B_c / \text{CIR}$ )

# IPv6 test-bed

- TCP traffic generated with Iperf 1.7.0 for Linux
- RTT < 4 ms

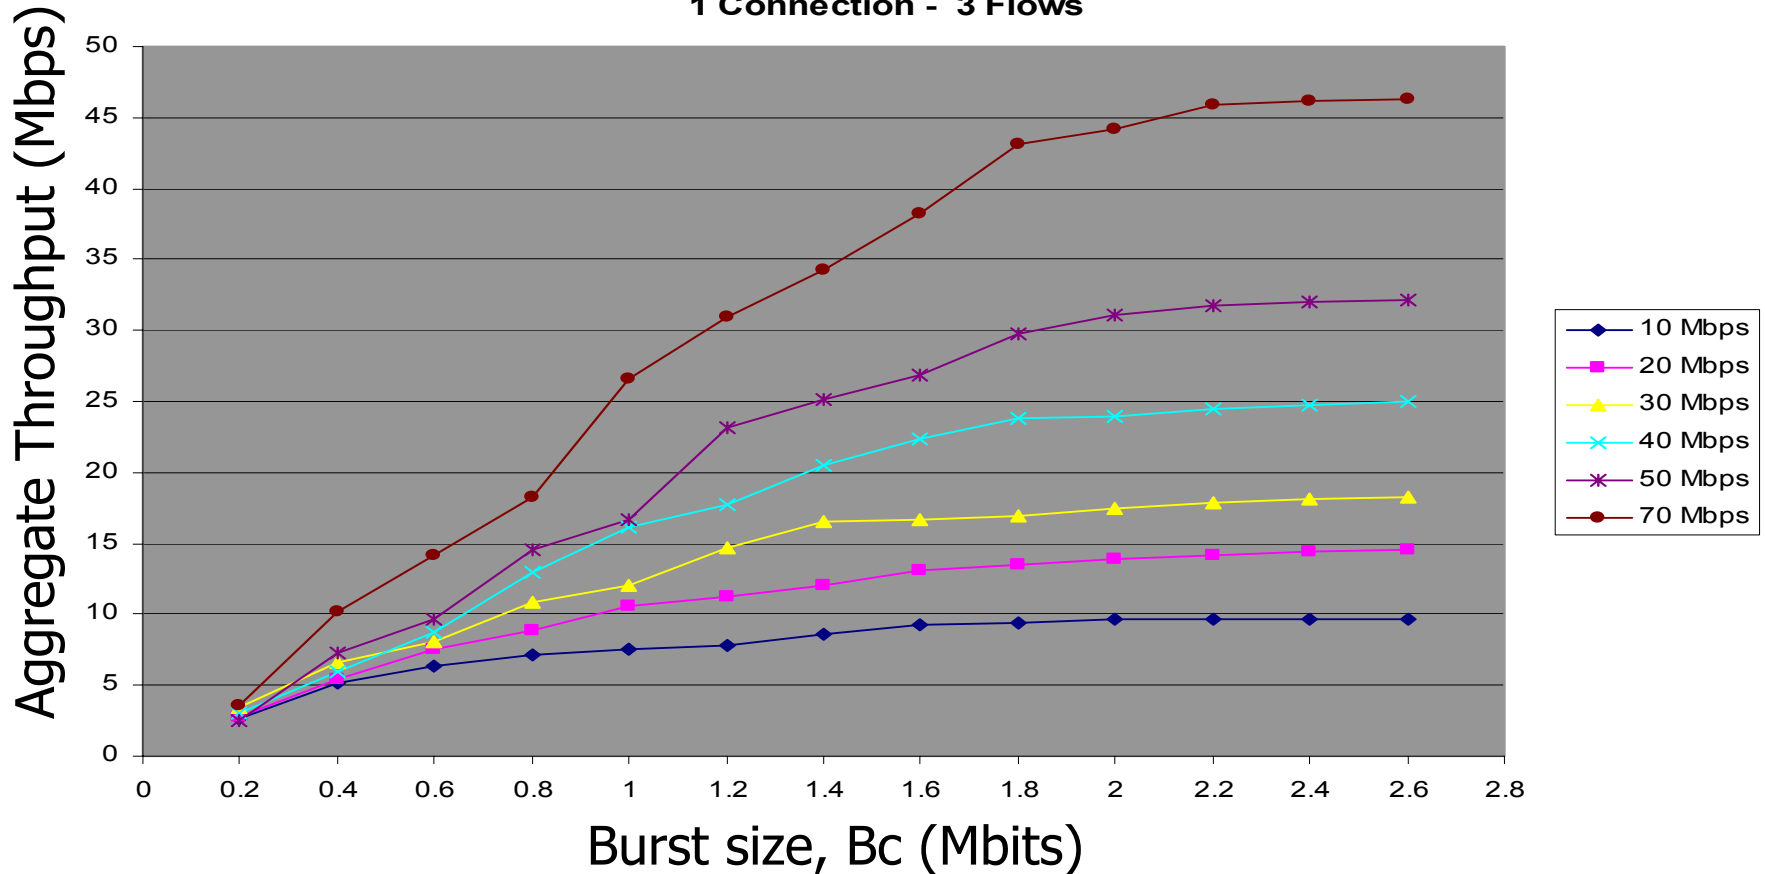

# Policing tests topology

- For **fixed policing rate**, measure **aggregate throughput** for **different burst sizes**

# Variable policing rates (1/3)

Only Policing (Router),  
Variable Policing Rate,  
1 Connection - 3 Flows

## Variable policing rates (2/3)

---

- Aggregate **throughput increases** with **burst size**, but is always **< policing rate**
- For **higher rates** throughput is **proportionally smaller**
  - Rate = 10 Mbps -> Throughput = 9.7
  - Rate = 70 Mbps -> Throughput = 46
- Experiments for both Cisco & Linux routers gave identical results

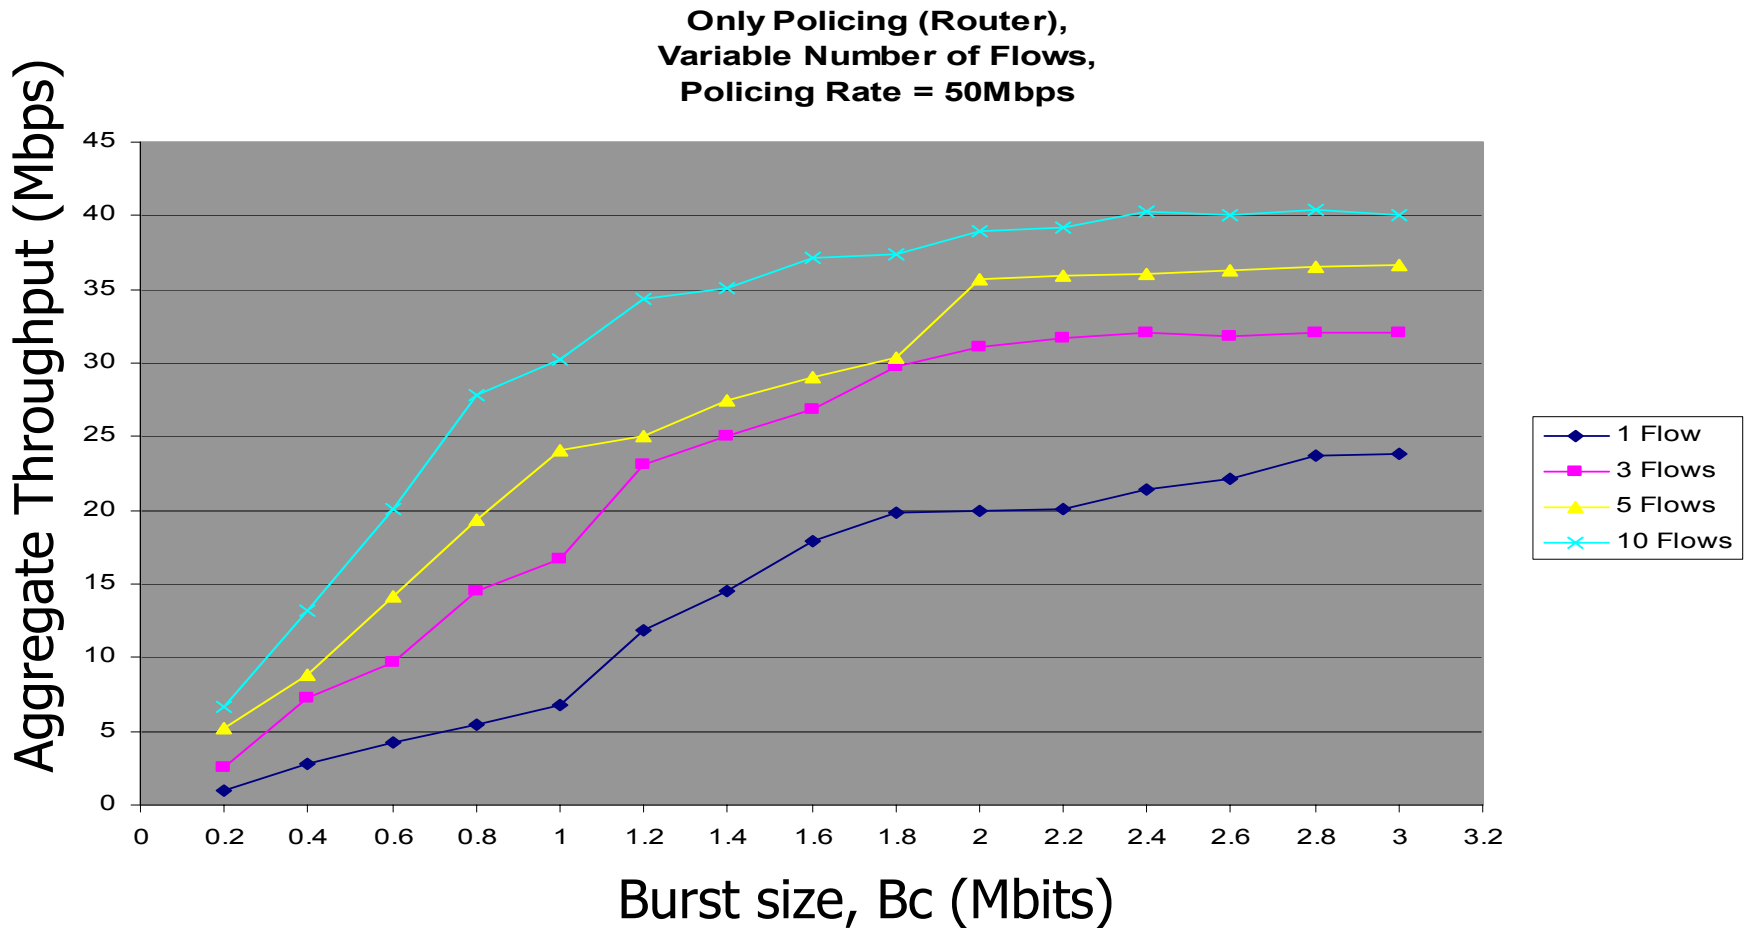

## Variable policing rates (3/3)

---

- Throughput versus burst size exhibits a “knee” at  $Bc^*$ , which is approximately:
  - If Rate < 40Mbps,  
 $Bc^* = 0.6 \text{ Mbit} + 0.03\text{sec} * \text{Rate}$
  - If Rate > 40Mbps,  
 $Bc^* = 1.5 \text{ Mbit} + 0.01\text{sec} * \text{Rate}$
- Burst Size > RTT\*Rate **not sufficient!**

# Variable number of flows (1/2)

## Variable number of flows (2/2)

---

- Optimum burst size (“knee” value) is **independent** of the **number of flows**
- Aggregate throughput **increases with number of flows** (multiplexing)
- Similar results for Cisco & Linux routers

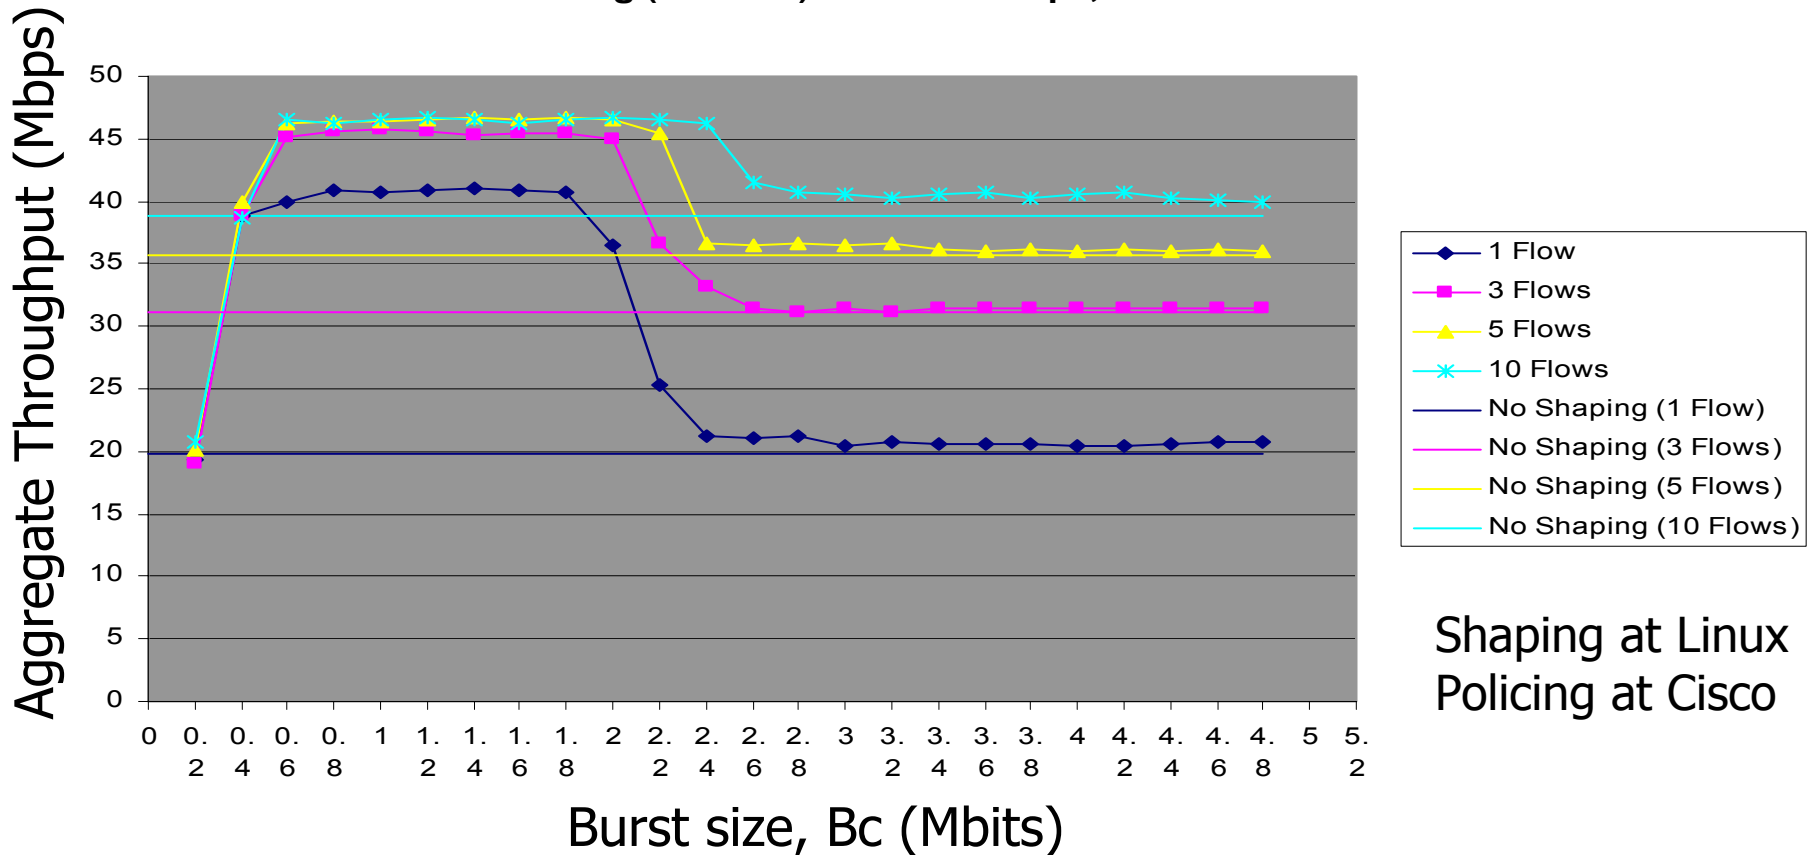

# Interaction of policing & shaping

- For fixed **rate & burst size of policer** and **rate of shaper**, measure **aggregate throughput** for different burst sizes of shaper

# Throughput vs. burst size (1/4)

Interaction of Policing and Shaping,  
Variable Number of Flows,  
Shaping (Router1): Rate = 50Mbps, Buffer Limit = 1000pkts,  
Policing (Router2): Rate = 50Mbps, Bc = 2Mbits.

# Throughput vs. burst size (2/4)

---

- Appropriate shaper burst size can lead to significant **throughput increase**
  - Throughput is always higher with shaping
  - Setting **burst size of shaper = burst size of policer** not always optimal
- **Low throughput for very small burst sizes**
  - Due to overflow at shaper's queue
- But also, **very large burst size** gives **low throughput**
  - Very large burst sizes allow large bursts which lead to multiple drops at the policer

# Throughput vs. burst size (3/4)

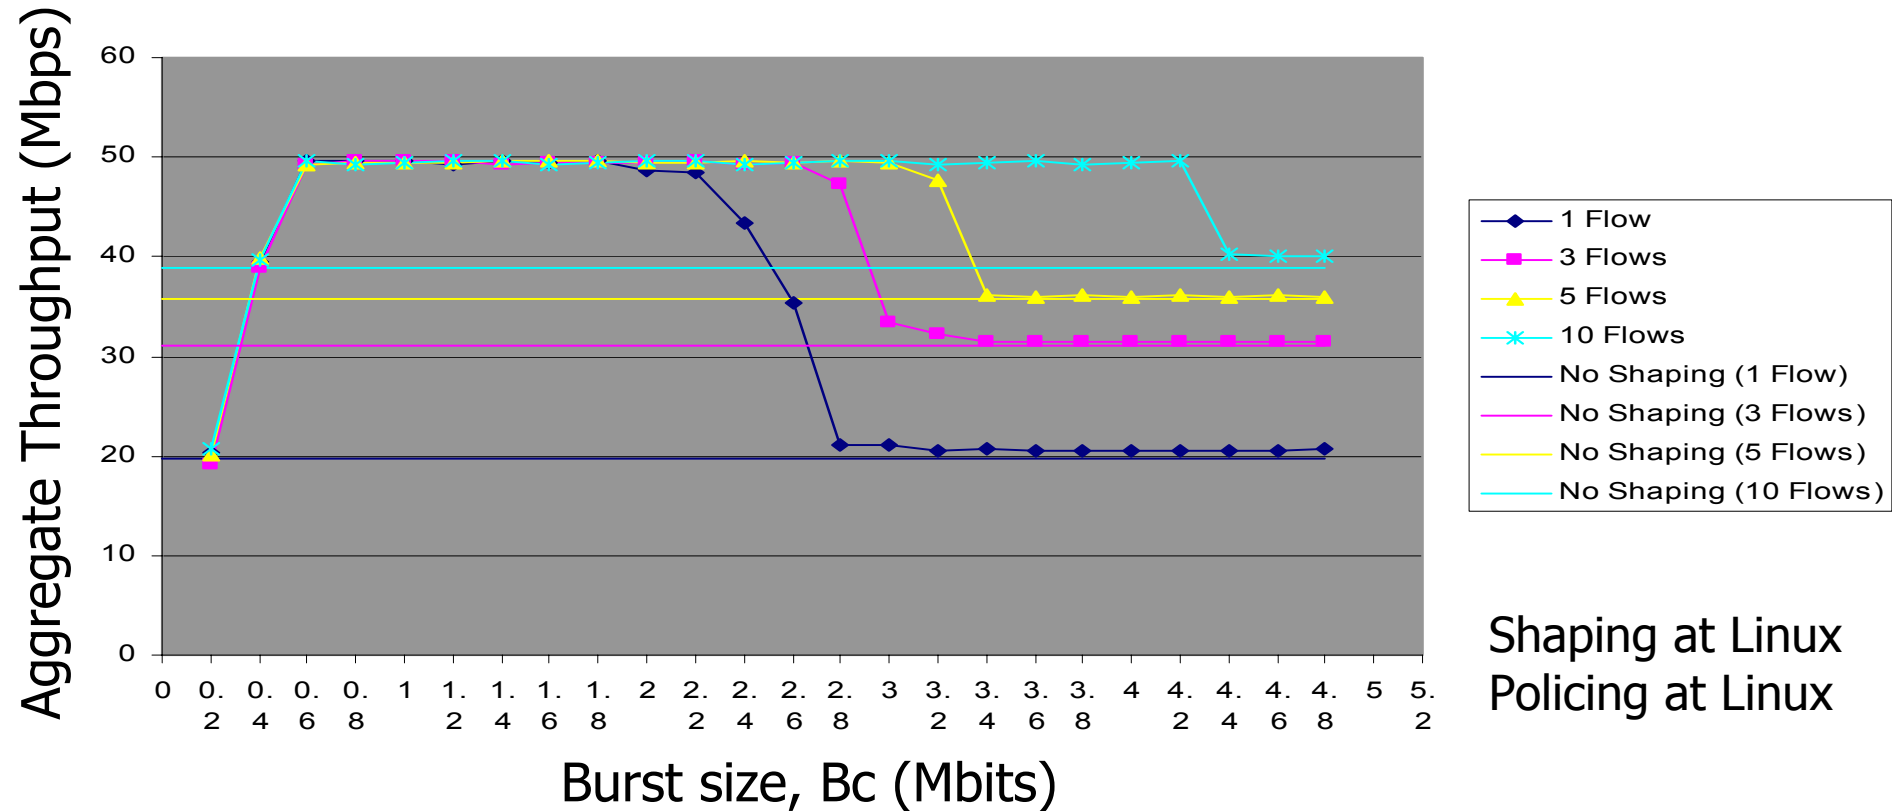

---

- For larger # of flows there is larger range of burst sizes that achieve maximum throughput

# Throughput vs. burst size (4/4)

No qualitative difference when using two Linux or Linux & Cisco routers

Shaping at Linux  
Policing at Linux

# Throughput vs. shaping rate (1/2)

Interaction of Policing and Shaping,  
Variable Number of Flows,

Shaping (Router1): Bc = 2Mbits, Buffer Limit = 1000pkts,  
Policing (Router2): Rate = 50Mbps, Bc = 2Mbits.

Shaping at Linux  
Policing at Cisco

Policing rate

Aggregate Throughput (Mbps)

Shaping Rate (Mbps)

- 1 Flow
- 3 Flows
- 5 Flows
- No Shaping (1 Flow)
- No Shaping (3 Flows)
- No Shaping (5 Flows)

## Throughput vs. shaping rate (2/2)

---

- Throughput maximum for **shaping rate** a little higher than **policing rate**
- **Very high shaping rates** leads to **throughput degradation**, due to bursts that are allowed by the shaper

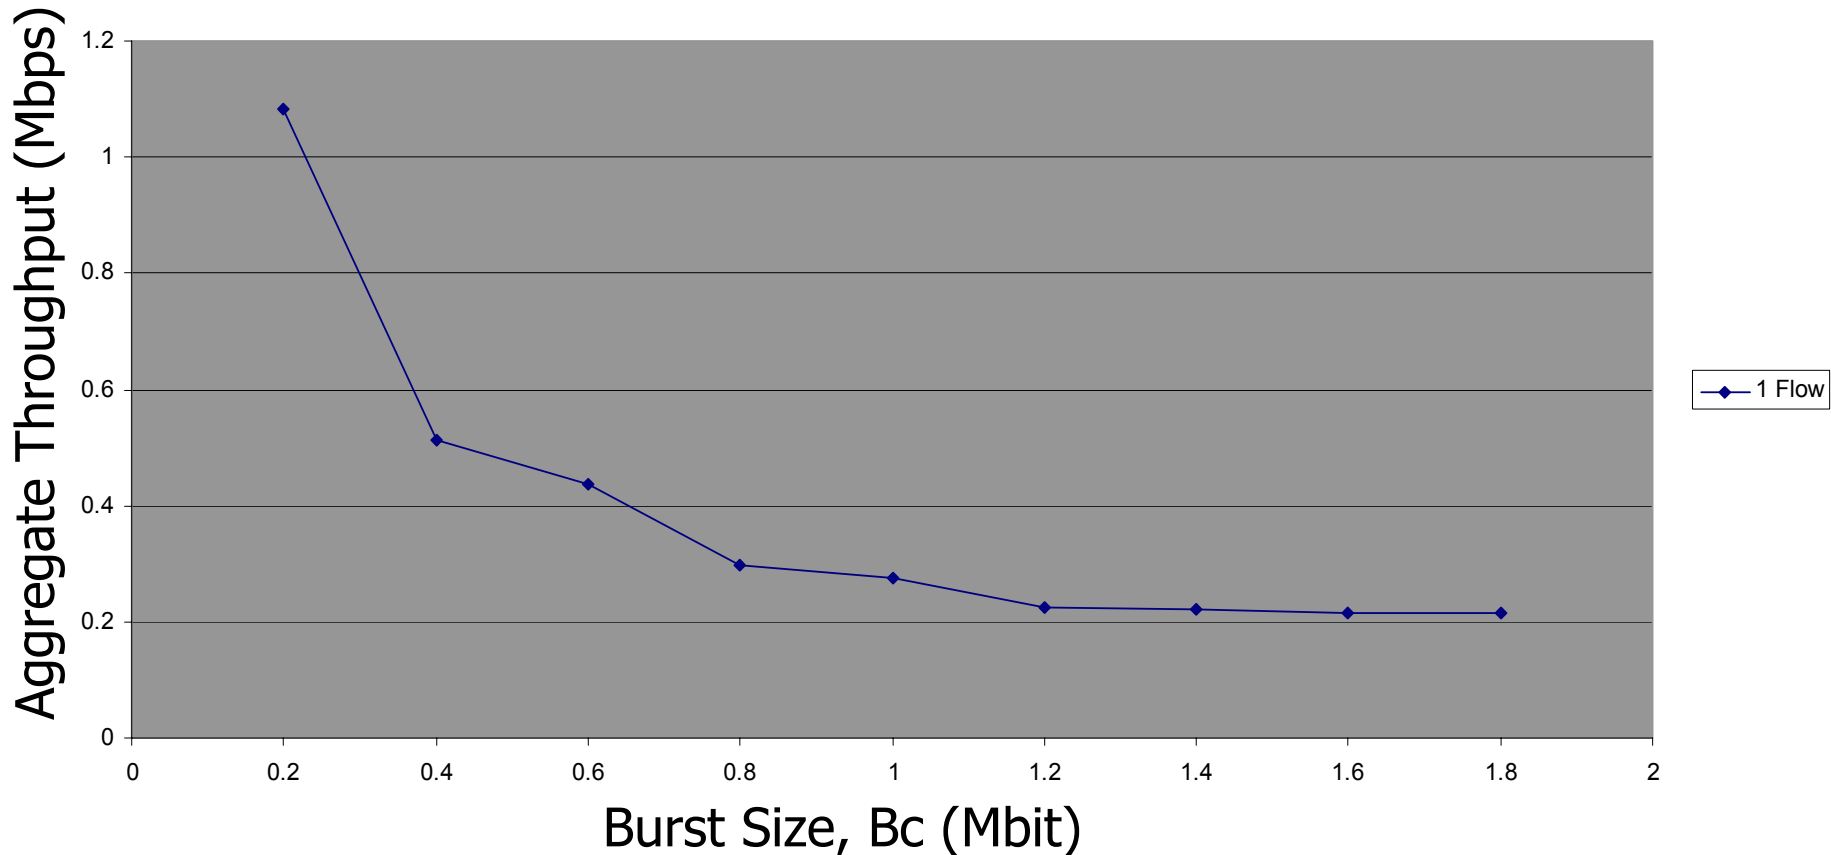

# Delay jitter tests (1/3)

---

- Policing/Shaping tests showed there is a **range of shaper burst sizes** for which **throughput is maximized**
- Which burst size is **best**?
- Answer: **consider delay**

# Delay jitter tests (2/3)

Interaction of Policing and Shaping,  
Shaping (Router1): Rate = 50Mbps, Buffer Limit = 1000pkts,  
Policing (Router2): Rate = 50Mbps, Bc = 2Mbits.

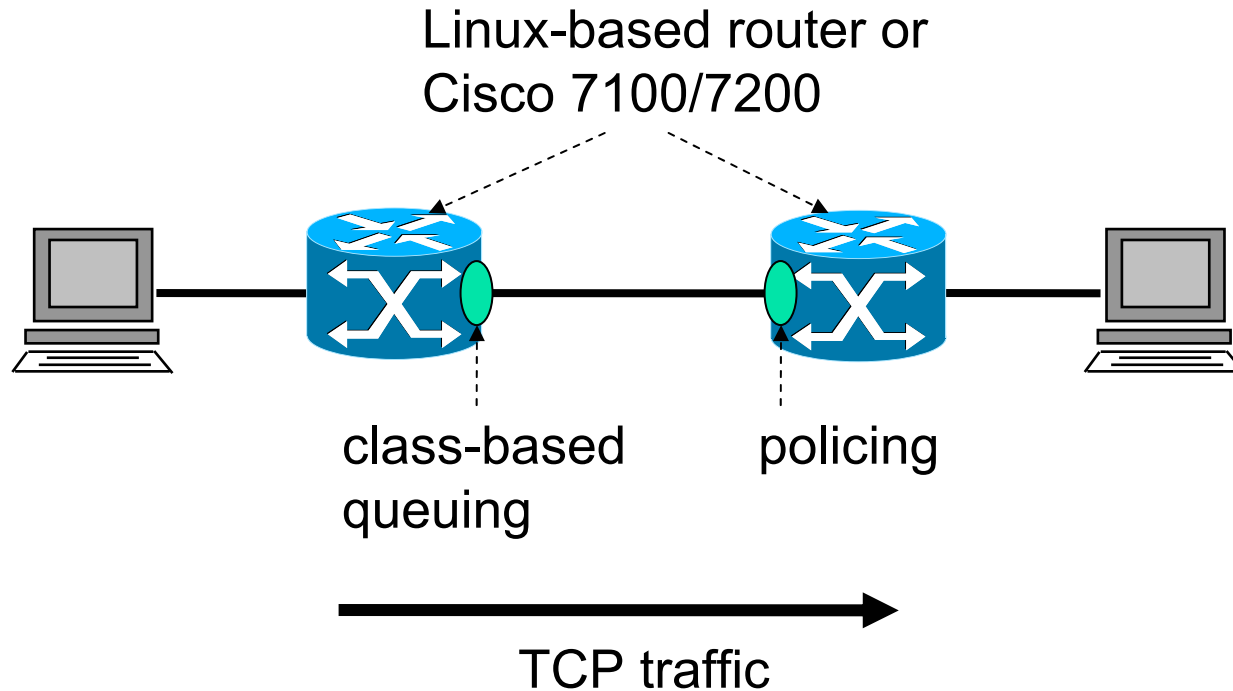

## Delay jitter tests (3/3)

---

- Jitter decreases when burst size increases
- Optimal burst size is one for which delay jitter is smallest, but is in the range of values that maximize throughput

# Interaction of Policing and Class Base Queuing

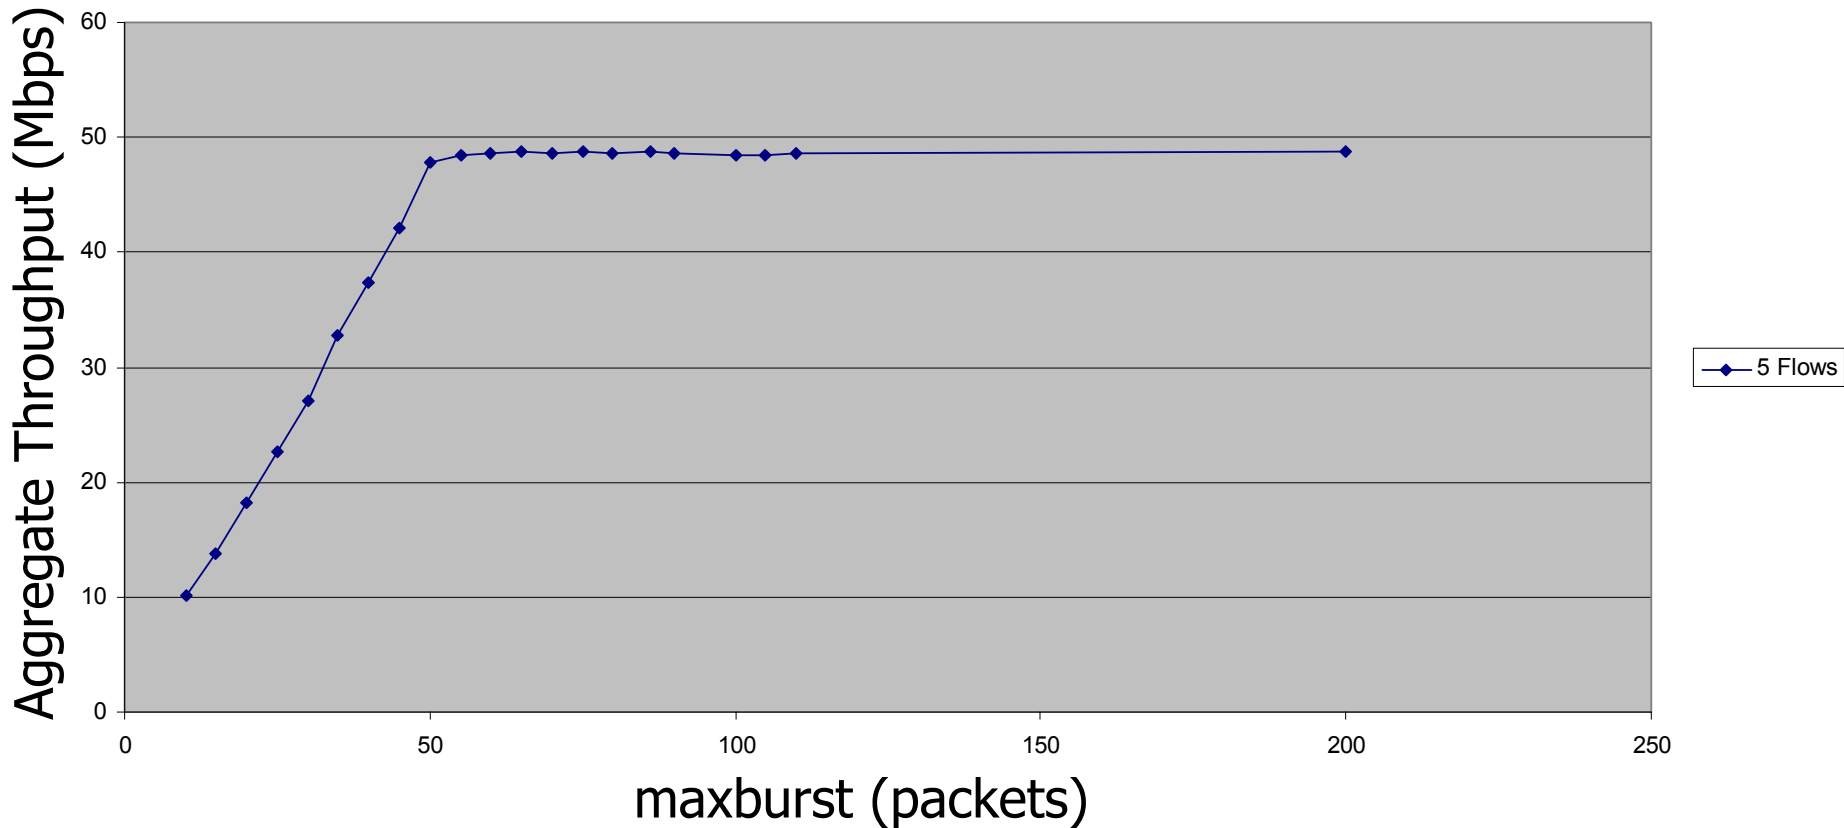

- For **fixed rate & burst size of policer** and rate of CBQ, measure **aggregate throughput** for **different maxburst** values

# Variable *maxburst* at CBQ (1/2)

Interaction of CBQ and Policing,  
CBQ (Router1): Rate = 50Mbps  
Policing (Router2): Rate = 50Mbps, Bc = 2Mbits,

CBQ at Linux  
Policing at Cisco

## Variable *maxburst* at CBQ (2/2)

---

- Maximum throughput achieved with appropriate *maxburst* value
- Low throughput for small *maxburst*
- Large *maxburst* values do not result in throughput degradation
  - *maxburst* has different effect than burst size in shaping
  - CBQ performs traffic smoothing

# Conclusions and outlook

---

- Interaction of QoS mechanisms is important for effectively supporting SLAs
- In the presence of policing, shaping can increase aggregate throughput
  - Must appropriately set shaping parameters
- Tuning of parameters should consider throughput & delay
- Similar behavior with Cisco/Linux, IPv6/IPv4
- Further research directions:
  - Experiments in wide area (larger RTT)
  - Experiments in wireless networks

# A test-bed investigation of QoS mechanisms for supporting SLAs in IPv6
